**Abstract** – This work aims at the design of a roped elevator prototype, which uses a linear induction motor (LIM) as a traction machine. It is also concerned with the development of a specific inverter to feed the linear motor that allows several ways to drive the elevator through a suitable choice of the RMS voltage levels, angular phase displacement and electrical frequency of the output voltage. The result tries to establish a new concept for elevators through a new construction technique and assembly of the system with counterweight, which increases the reliability and comfort with cost reduction.

**Keywords** – drives, elevators, linear induction motor, power electronics.

## I. INTRODUCTION

Nowadays, the vast majority of applications, that a linear motion is necessary. It uses a rotary electrical motor as source of motion in order to convert the rotary motion into a linear motion. Often, it is necessary to use a complex mechanical system of gears, axles and screws jacks. When used directly, these transmission systems for movement have great losses. Among the reasons is the increased abrasive wear due to the friction of the mechanical parts, even when using low viscosity fluids for the lubrication. This results into higher operational and maintenance costs [1]. Therefore, for transport applications, the use of an electrical machine that produces directly the linear motion would result in lower operational and maintenance costs as well as higher reliability and efficiency [1, 2].

This work intends to build an elevator prototype system using a linear induction motor, fed by a suitable converter, which takes into consideration the desired drive.

## II. LINEAR MOTORS

The linear motor design can be obtained by geometrically arranging of a rotary motor into a linear configuration; along the radius of the rotary motor, from the center of the shaft to the external surface of the stator core. The motor is rolled out flat as it is schematically shown in Fig. 1. Therefore, for each type of rotary electrical machine (synchronous, inductance, reluctance and direct current) there is a linear equivalent. Linear motors were first developed at the end of eighteen century at the same time with the other rotary electrical machines [1].

Difficulties in driving the linear motor, that are due to its operation characteristics as well as the problems due to the longitudinal end and transverse edge effects that exist in linear machines, restricted its use to a few applications [1].

Initially, AC motor drives had fixed supply voltage and frequency and the required increased complexity in linear motor drives was not available, imposing limited use of linear machines. This resulted in turning the linear machines simply into a theoretical reference for almost the entire first half of the XX century [2].

Fig. 1. Imaginary building process of a linear induction motor (LIM).

The development of power electronics associated with the microprocessor allowed speed control, adjustment of the thrust and breaking control for improved efficiency and security. Thus, some applications are becoming advantageous when compared with the equivalents driven by rotary electrical machines [2, 3].

The perspectives of future applications of the linear machines in the industry are each time more promising, such as: pallet transportation, belt conveyors transportation of bulk material, machine tools, presses mills, separators, automated manufacturing systems, strip tensioners, textile shuttles, turntables, disc saws, military and aerospace applications, hypervelocity, ship propulsion and submarines, biomedical applications, elevators, load transport.

## III. LINEAR MOTORS IN ELEVATORS

The linear motor has been studied for the vertical conveying application because its main characteristic is the linear motion, which takes place without transformation mechanisms, increasing the efficiency and the reliability of the system and also eliminating the need for a bulky machine room on the roof [4].

Since the beginning of the research for the use of the linear motor in vertical drives, the type of the electrical machine i.e. synchronous, induction (Single or double sided and tubular) and reluctance or the configuration to be used became a great source of discussion among the researchers [5, 6, 7, 8, 9]. Many authors [5, 7, 8, 10, 11] extended and improved first approaches about elevators, e.g. the motor does the work of dislocating all the traveling weight (ropeless) or one can use a rope with counterweight (roped) decreasing thrust supplied for the motors, but the experimental work is generally missing. However the best configuration for such application is a problem to be solved. It is already expected that linear motors can generally

provide several important advantages when compared with configurations based on rotary motors [4]:

- Performance of the linear motors is comparable to that of rotary motors;
- Smooth operation and high comfort of riding can be obtained;
- Greater adaptability to the environment (building), e.g. penthouse machine room is not required, reduction of overhead space;
- It is possible to use the linear motor as a brake;
- Linear motor acts not only as a driving device but also as part of the counterweight;
- Energy saving and reduction in power capacity are possible.

#### IV. DESIGN OF A COUNTERWEIGHT ELEVATOR PROTOTYPE USING A LINEAR MOTOR DRIVE

Several design criteria have been applied to the LIM configuration and are listed as follows.

- 1) The elevator system will be shuttled by a double sided LIM;
  - 2) The LIM will be used as traction machine and counterweight;
  - 3) The linear motor must have a reduced size, due to the height (3m) conditions of the laboratory (GPAR) of the Department of Electric Engineering;
  - 4) This LIM must have a low speed, thus the maximum cruising speed was limited to 1.2m/s for a frequency of 20 Hz;
  - 5) The primary core will have opened rectangular slots;
  - 6) The LIM will carry the weight of the car structure plus the payload, thus the rated force will be of 200N;
  - 7) Rated voltage of 220 volts;
  - 8) The mechanical structure of the elevator prototype will be designed for 3m height;
  - 9) The elevator prototype will have along the path two stops (two floors);
- With the specified design criteria parameters the motor was designed according to the section V and then, the mechanical structure of the elevator was built.
- After that, the inverter was designed and finally were used a microprocessor (PIC16F877) to control the position of the elevator in each floor and a digital signal processor (TMS320F2812) to control the inverter itself (switching, breaking, acceleration).

#### V. DESIGN OF A DOUBLE-SIDED LINEAR INDUCTION MOTOR

The theoretical design of a LIM begins with the calculation of the main dimensions, i.e. pole pitch, number of slots, slot pitch, slot width, tooth width, length of the primary and width of the primary.

The airgap between the primary and secondary cores is designed to be 1mm, as shown in Fig. 2.

Oriented silicon steel sheets are used to assembly the primary core and to use all the sheet extension (450x100mm), the primary core has 12 magnetic poles.

The geometry sizes for a LIM are obtained from the design procedure stated below.

The pole pitch is:

$$\tau = \frac{v_r}{(1-s) \cdot 2 \cdot f} \quad (1)$$

Where:

- $v_r$  - Desired speed.
- $\tau$  - Pole pitch.
- $f$  - Electrical frequency.

Fig. 2. LIM geometry.

The length of the primary core is given by:

$$L_\tau = (2 \cdot p \cdot \tau + wc + c_1) \quad (2)$$

Where:

- $L_\tau$  - Length of the primary core.
- $p$  - Number of pairs of poles.
- $wc$  - Coil pitch.
- $c_1$  - Tooth width.

The yoke height of the primary core is the portion of the core above the teeth, as shown in Fig. 2. The flux in the yoke is one-half of the flux in the air-gap [12]. The required height of the yoke in order to carry the flux without excessive saturation can be expressed as:

$$\Phi_{pole} = 2 \cdot \Phi_{yoke}$$

$$h1y = \tau \cdot \frac{B_{mz}}{2 \cdot B_{mly}} \quad (3)$$

Where:

- $\Phi_{pole}$  - Flux per pole.
- $\Phi_{yoke}$  - Flux in the yoke.
- $B_{mz}$  - Average air gap flux density for one pole pitch.
- $B_{mly}$  - Assumed magnetic flux density in the yoke.
- $h1y$  - Height of the yoke of the primary core.

For the type of motors being considered, a thrust of 2000 N/m<sup>2</sup> can be produced without any excessive heating in the primary winding [12, 13]. Based on the above dimensions the width of the primary core is:

$$Li = \frac{F}{L_\tau \cdot \xi} \quad (4)$$

Where:

- $L_i$  - Width of the primary core.
- $\xi$  - Desired specific thrust per square meter

The primary slot pitch have width dimension, given by:

$$t_1 = \frac{2 \cdot p \cdot \tau}{z} \quad (5)$$

Where:

- $t_1$  - Slot pitch.  
 $z$  - Number of slots.

To avoid magnetic saturation in the primary teeth, there is a minimum value of tooth width (see fig.2), which depends on the assumed magnetic flux density in the tooth.

The magnetic flux per pole is three times the magnetic flux per teeth [14]. Hence the tooth width can be calculated with:

$$\Phi_{pole} = 3 \cdot \Phi_{tooth}$$

$$c_1 = \frac{t_1 \cdot B_{mz}}{B_{m1t}} \quad (6)$$

Where:

- $B_{m1t}$  - Assumed magnetic flux density in the tooth.

The slot pitch is the sum of the slot width and the tooth width and hence the slot width can be calculated with:

$$b_{11} = t_1 - c_1 \quad (7)$$

The primary core has 39 slots and was determined from:

$$z = 2 \cdot p \cdot m \cdot q \quad (8)$$

Where:

- $m$  - Number of phases.  
 $q$  - Number of slots per poles per phases.

For a three-phase configuration of 12 poles, the LIM was designed with a double-layer distribution in the thirty three central slots and a mono-layer in the six slots at utmost point, concerning three in the entrance slots and three at end of exit slot, as shown in Fig. 3.

Fig. 3. Winding configuration of the primary core.

This configuration of winding together with length extension of the primary stack tries to reduce the longitudinal end effects [2].

The winding of the primary core has 198 turns per slot using the wire gauge of #22AWG (0,33mm<sup>2</sup>) given by:

$$N_1 = \frac{V_1 \cdot k_v}{\sqrt{2} \cdot \pi \cdot f \cdot k_{w1} \cdot B_{mz} \cdot Li \cdot \tau} \quad (9)$$

Where:

- $N_1$  - Number of turns per phase.  
 $k_v$  - Voltage drop factor.  
 $k_{w1}$  - Winding factor.  
 $V_1$  - Input phase voltage

Therefore, the number of turns per slot is:

$$N_{sl} = \frac{N_1}{p \cdot q} \quad (10)$$

Where:

- $N_{sl}$  -Number of conductors in each slot.

The height of the slot  $h_{11}$  can be determined as follows:

$$h_{11} = \frac{N_{sl} I_1}{p \cdot q \cdot J \cdot k_{fill}} \quad (11)$$

Where:

- $J$  - Current density in the primary winding.  
 $k_{fill}$  - The slot fill factor.  
 $I_1$  - Current in the primary winding

The dimensions from the design of the primary core are depicted in Table 1.

**TABLE I**  
**Size of the primary core**

Quantity	LIM	Unit
Length of primary core, $L_c$	450	mm
Width of primary core, $L_s$	70	mm
Pole pitch, $\tau$	30	mm
Height of the yoke, $h_{ly}$	30	mm
Height of the slot, $h_{11}$	30	mm
Height of primary core, $(h_{11}+h_{ly})$	60	mm
Tooth width, $c_1$	5	mm
Slot width, $b_{11}$	5	mm
Slot pitch, $t_1$	10	mm

The winding and the primary core final result of the linear motor designed are depicted in Fig. 4.

Fig. 4. Linear motor designed.

The secondary core was assembled with aluminum sheets with 3000x5.6x12mm, due to the good magnetic current conductivity and the poor magnetic conductivity.

The width of the aluminum secondary core is assumed as the same as the width of the primary core. The aluminum secondary sheet of a LIM is equivalent with the cage rotor of a rotary motor [2].

## VI. MECHANICAL STRUCTURE

For the mechanical structure development, the linear motor was thought as a counterweight due to its mass characteristics and at the same time produces the traction force.

As shown in Fig. 5, it is possible for both primary cores to precisely adjust the gap through the screws.

Fig. 5. Primary core structure.

Fig. 6 shows the assembled mechanical structure. All the structure is shaped by T section angles and square tube sections of 1020 steel and 1/4 inch. The mechanical structure is open without walls, easily allowing small adjustments if necessary.

Fig. 6. Elevator structure designed.

## VII. DOUBLE THREE-PHASE BRIDGE VOLTAGE SOURCE INVERTER DRIVE

For this project, it was decided to design an inverter that fulfills the condition to supply the motor with unbalanced currents in each winding. Considering that this experimental setup in the future will be used to fulfill several essays, as

driving the LIM with unbalanced currents (each phase with a different angular displacement). These essays are requested for future works in this laboratory. Therefore the inverter that fulfills the imposed conditions is the double-bridge inverter as shown in Fig. 7.

Fig. 7. Double three-phase bridge basic circuit.

Note that this type of inverter is essential three single-phase bridges. And to avoid the short circuit the three-phase load must either be separated into three electrically isolated single phase loads (see Fig 7.) or a transformer must be used to provide electrical isolation [15].

The Pulse width modulation (PWM) strategy used is known as unipolar modulation [16], where one phase leg is modulated in the first half of output voltage period, while the other phase leg is modulated in the second half of output voltage period, as shown in Fig. 8.

In this strategy on the first half cycle, the IGBTs S1 and S4 are modulated, while the IGBTs S2 and S3 are turned off. After, on the second half cycle the sequence is inverted (S1 and S2 are turned off; S2 and S3 are modulated).

## X. CONCLUSION

In this work the theoretical and experimental study of a counterweight elevator using a linear induction motor was presented. An elevator prototype using a LIM was built and experimentally tested, consisting of the mechanical structure of the elevator, the electromagnetic brake system, the drive and control unit.

As the double-bridge inverter is equivalent to three full-bridge inverters, the DSP can control independently each one of them, that is, to impose output voltage levels, angular displacement and output frequency separately. Therefore, the use of this inverter becomes an important tool to impose different feeding conditions (unbalanced currents) for future analysis, as the determination of LIM parameters from the equivalence between LIM and the ordinary asymmetrical rotary induction motor [18].

With the use of this technology, a paradigm break may occur due a new elevator construction method, not existing in the standards.

Therefore, using the linear motor to drive an elevator, the passenger may have better ride quality and comfort in the ascent and descent, due to the speed control [4]. Easier maintenance and inspection access due to the motor topology.

No penthouse machine room is available, in conclusion using a linear motor elevator, considerable building space can be saved and more space can be profitable rented [10].

Load optimizations, high speed, no gear-reductions, saving energy are the other important advantages.

The application of this technology aims at warehouses, ports, industrial and commercial elevators.

## ACKNOWLEDGEMENT

The authors would like to thank financial support of FUNCAP, the financial support of Brazilian Agencies CNPq and Texas Instruments for providing the DSP platform.
